ABSTRACT

We present a near-infrared J , H , K and L' band ($1.25 - 3.80 \mu\text{m}$) imaging study of a sample of Seyfert galaxies, including some of the best studied examples of those with extended emission line regions (EELR). The observed near-IR nuclear colors are consistent with a mixture of emissions from an old stellar population and unreddened hot dust. However, if the hot dust is located in the inner part of the dusty torus invoked in unified schemes, the dust emission should suffer substantial reddening. We show that the near-IR nuclear colors may also be reproduced with a combination of emission from unreddened starlight and hot ($T = 1200 \text{ K}$) dust reddened by $A_V \approx 5 - 30 \text{ mag}$. All of the galaxies exhibit an unresolved nuclear source at L' . The circumnuclear colors (in a $0.5 - 1.0 \text{ kpc}$ annulus) are similar to those of normal spiral galaxies in most cases, although some galaxies exhibit extended emission at L' , presumably from hot dust, causing the circumnuclear $K - L'$ colors to be redder than for normal galaxies. We argue that the circumnuclear hot dust in NGC 1068 and NGC 4151 is probably heated by young stars.

A detailed study of the morphologies of the central and circumnuclear regions of the galaxies in our sample is presented. We have constructed smooth models of the old stellar population by fitting elliptical isophotes to the J and K band images. The model-divided images are examined for the presence of isophotal deviations from elliptical symmetry, such as internal bars, spiral arms, etc, and compared with the structures seen in optical emission-line images, to study the relative orientations of bars, the EELRs, the nuclear radio emission and the host galaxy. We find stellar bars in NGC 1068 and NGC 4253 whose orientations are consistent with those of their EELRs and evidence for double bars (or “bars within bars”) in Mrk 573, NGC 3081 and NGC 3393. Only in

NGC 2110 and NGC 4151 do we find no significant isophotal deviations from elliptical symmetry. Finally there is an alignment on small scales between the near-IR continuum and the line emission in four galaxies, NGC 1068, NGC 2110, NGC 3081 and NGC 4253. These results seem to suggest that there is not a unique explanation for the orientation of the EELRs seen in Seyfert galaxies. In some cases, the EELRs could represent gas aligned with the nuclear stellar bars, whereas in others, they are more likely to be related to gas escaping along the minor axis of the galaxies.

INTRODUCTION

The unified model for active galactic nuclei (AGN) explains the observed differences between certain types of AGN in terms of an orientation dependence of some preferred axis with respect to the observer (see Antonucci 1993 for a recent review). The main observational evidence for such a scheme comes from spectropolarimetry, which reveals “hidden” broad-line regions (e.g., Antonucci & Miller 1985), and emission-line images which shows elongated morphologies for the extended emission-line regions (EELRs) in many Seyfert 2 galaxies (e.g., Haanff, Wilson, & Ward 1988). In some cases, the emission-line images exhibit striking conical or bi-conical structures (e.g., NGC 5252 Tadhunter & Tsvetanov 1989, NGC 5728 – Wilson et al. 1993 and NGC 5643 – Stupson et al. 1997). These “ionization cones” can be traced down to a few tens of parsecs from the nucleus (e.g., NGC 1068 – Evans et al. 1991; NGC 4151 – Evans et al. 1993), and the cone axis is generally aligned with that of the radio jet (e.g., within a few degrees (Wilson & Tsvetanov 1991).

In the unified scheme, these observations are usually explained by an optically-thick torus that surrounds the nuclear engine and the broad line region, obscuring them from view in Seyfert 2 galaxies. This torus is also able to collimate the radiation and produce the conical emission-line structures. Although this is an appealing model, there is currently little direct evidence for the existence of the torus itself, and different physical sizes and geometries have been proposed for the obscuring torus. Hot dust ($T = 1000 - 1300$ K) has been found to make an important contribution to the near-infrared (near-IR) emission from the centers of Seyfert galaxies (Glass & Moorwood 1985; Kotilainen et al. 1992b; Alonso-Herrero, Ward, & Kotilainen 1996b), and it is natural to consider the possibility that this dust lies within the torus. If the dust in the inner walls of the torus has a temperature $T \sim 10^3$ K then the inner edge of the torus must only be a few parsecs from the

nuclear continuum source (Krolik & Begelman 1988; Lawrence 1991) in good agreement with the models of the spectral energy distribution of NGC 1068 (Pier & Krolik 1993). The total extent of the torus, however, may be much greater, perhaps several hundred parsecs. Granato & Danese (1994) have fitted the spectral distribution energies of a sample of Seyfert galaxies with optically thick tori with ratios of the outer to the inner radius $3 \leq r_o/r_i \leq 3000$. Using more indirect arguments based on the relative numbers of Seyfert 1s, intermediate and Seyfert 2s, Maiolino & Rieke (1995) and McLeod & Rieke (1995) have suggested that the last two kinds of Seyfert galaxies are Seyfert 1s seen through a 100-pc inner radius torus coplanar with the galactic disk plane. Although there are few direct observational constraints on the geometry of the torus, high-resolution imaging has revealed structure in the centers of Seyfert galaxies which supports the torus picture. Red features have been found in color maps (e.g., Kotilainen & Prieto 1995, Simpson et al. 1996) and dust lanes have been observed in *HST* images (e.g., NGC 5728 Wilson et al. 1993; NGC 5643 Simpson et al. 1997), in all cases straddling the nucleus and oriented perpendicular to the radio/FELR axis. Although the resolution of these images is far larger than the scale of the inner radius of the torus, they indicate that dust has settled in the equatorial plane and these structures may be dynamically linked with the torus proper.

In this paper, we present near-IR imaging observations (from 1.25 to $3.80\mu\text{m}$) of a sample of Seyfert galaxies, many of which possess FELRs. This study was designed to carry out a detailed analysis of the innermost 0.5 and 1 kpc, as well as the larger scale structures of the galaxies. Smooth galaxy models are constructed by fitting elliptical isophotes, examined for isophotal deviations from elliptical symmetry, and compared with the morphology of the FELRs, in order to test whether there is any relationship between the FELRs and the circumnuclear regions when observed in the near-IR. The paper is organized as follows. In Section 2, we describe the observations and their reduction. Section 3 discusses the ~ 1 kpc-scale colors of the sample of Seyfert galaxies, and describes their *L'*-band properties

and the morphologies of their central and circumnuclear regions. The results are discussed in Section 4. Conclusions are summarized in Section 5.

2. OBSERVATIONS

We have obtained near-IR imaging of a sample of twelve Seyfert galaxies through J ($\lambda_c = 1.25 \mu\text{m}$), H ($\lambda_c = 1.65 \mu\text{m}$), K ($\lambda_c = 2.20 \mu\text{m}$) and L' ($\lambda_c = 3.80 \mu\text{m}$) filters. The Seyfert galaxies were selected according to the criterion that they show ionization cones or FELRs in $[\text{O III}] \lambda 5007$ and/or $\text{H}\alpha + [\text{N II}]$ images. The sample, which is not complete, is composed of type 1.5 through type 2 Seyfert galaxies, including some of the brightest and best studied examples of their class. The observations were carried out with the IR camera IRCAM3 on the 3.9-m United Kingdom Infrared Telescope (UKIRT) during two observing runs, 1995 January 2-5 and 1996 December 30, with pixel sizes $0''.286 \text{ pixel}^{-1}$ and $0''.143 \text{ pixel}^{-1}$ respectively. The size of the J , H and K images is 256×256 pixels, whereas the size of the L' images is 64×64 pixels. In some frames taken on the 1995 Jan run, wind shake produced an artificial E-W elongation of the images; the shape of the images in the inner few arcseconds should be treated with caution. For this reason, new images of seven galaxies were obtained in the 1996 Dec run with a smaller pixel size and using a rapid guider, which greatly reduces the effects of wind shake and improves the image quality. Conditions in the 1996 Dec run were non-photometric. The sample is presented in Table 1, where the last column indicates the observing runs and filters in which the galaxy was observed.

The observational procedure involved taking several images of the galaxy which were alternated with adjacent blank areas of sky with the same number of coadds and on-source integration times. The sky images were used for both flat-fielding and sky background subtraction. The individual object frames were offset a few arcseconds so that residual pixel-to-pixel sensitivity variations and the effects of bad pixels were minimized. Standard

reduction procedures, involving dark-current subtraction, flat-field correction, bad pixel removal, background subtraction, and individual galaxy image registration, were used.

Conditions were photometric during the 1995 Jan run so standard star observations were used to perform the photometric calibration of the images. A number of standard stars taken from the list given in Elias et al. (1982) were observed several times throughout each night and reduced in a similar way. A flux calibration solution for each filter was calculated for the entire set of standard star observations, as no systematic variations were found between different nights. The calibration was determined using a three parameter regression (zero point, extinction coefficient and color term). The major source of uncertainty in near-IR observations comes from the background subtraction. The size of the J , H and K 1995 Jan images is large enough that most of the galaxies do not fill the detector field of view, allowing us to measure the residual sky level uncertainties in blank areas. These uncertainties were found to be less than 0.5% of the original sky background, and no systematic positive residuals are present, indicating that in most cases the galaxy light does not fill the image. In the case of the L' -band imaging, we find that the majority of the galaxies are compact, again allowing us to quantify the uncertainties associated with the background subtraction in blank areas on the edges of the images. Because of the higher variability of the sky at this wavelength, the uncertainties tend to be larger, 2 - 3% of the original sky value. Typical errors from the photometric calibration are 0.09, 0.04, 0.08 and 0.04 mag in J , H , K and L' , respectively. Since the observing conditions during the 1996 Dec run were non-photometric, the magnitudes from the 1995 Jan observations were used to flux-calibrate the images by means of multiple aperture photometry. Due to the smaller pixel size of the 1996 Dec observations, we were able to measure magnitudes and colors for a $1.5''$ -diameter aperture, with errors typically between 5 and 10 % (due to the uncertainties on the sky background value). The full width half maximum (FWHM) was measured from the standard stars and stars on the galaxy frames as 1 - $1.2''$ and 0.7 - $1''$ at K band for

1995 Jan and 1996 Dec runs respectively.

Standard synthetic aperture photometry was performed on all the 1995 Jan near-IR images using the IRAF APPHOT routines. Circular apertures were used to obtain magnitudes for each object. The magnitudes were measured through 3, 6, 9, 12, 15 and 30'' (when possible) diameter apertures in the *J*, *H* and *K* images, and 3 and 6'' (when possible) diameter apertures in the *L'*-band images (1995 Jan data). Note that in the case of Mrk 463E+W, 2 and 4'' diameter apertures were used to allow us to get measurements for both nuclei. As noted above, when 1.5''-diameter aperture photometry is given, the data correspond to the 1996 Dec run. Good agreement (to within 20%) is found when comparing our results with previously published aperture photometry (Glass & Moorwood 1985; Boisson & Durret 1986; Kotilainen et al. 1992a; McLeod & Rieke 1995; Alonso-Herrero et al. 1996b). At the bottom of Table 2 we list the average sky brightness of the sky for each filter as measured from the images taken on the 1995 Jan run.

3. RESULTS

The aperture photometry is presented in Table 2, in which column (2) gives the integration times in seconds for each filter for the 1995 Jan data and, enclosed in brackets, for those galaxies observed on 1996 Dec. Columns (4) through (7) are the *J* - *H*, *H* - *K* and *K* - *L'* colors and the *K*-band magnitude respectively. Contour plots on a logarithmic scale of the 256×256 pixel *J*- (the *H* and *K* band images show similar morphologies) and 64×64 pixel *L'*-band images (1995 Jan data) are presented in Figure 1. The *L'*-band images have been plotted on the same scale as the *J*-band images to allow a direct comparison of sizes and orientations in the nuclear regions. At the top of the *L'*-band panel of each galaxy the linear size corresponding to 10'' has been indicated (at the distances calculated from the heliocentric velocities listed in Table 1, assuming $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$). It is clear

from this figure that in most cases the L' -band emission is confined to the nuclear regions with, at most, a small contribution from the underlying galaxy. This point will be discussed in more detail in Section 3.2.

3.1. The near-IR colors of the central and circumnuclear regions

Previous studies of the near-IR continuum of Seyfert galaxies (Glass & Moorwood 1985; Kotilainen et al. 1992b; Alonso-Herrero et al. 1996b) concluded that their $J - H$, $H - K$ and $K - L$ nuclear colors can be explained by a model involving a normal stellar component plus a hot dust component in emission. Alonso-Herrero et al. (1996b) also showed that the $K - L$ color is more sensitive to the presence of hot dust and less affected by extinction than other near-IR or optical colors. This study, however, suffered from a lack of sensitive small-aperture L band ($\lambda_c = 3.4 \mu\text{m}$) measurements, since only a few galaxies were imaged in this filter. The present study offers a number of advantages. First, a smaller pixel size was used to obtain more reliable small-aperture measurements. Second, both the good photometric and seeing conditions during the 1995 Jan run allowed us to produce more accurate magnitudes and colors (note that approximately 50% of the observations in Alonso-Herrero et al. 1996b had to be calibrated with previously published photometry). Third, good-quality L' -band imaging data were obtained for most of the galaxies in our sample.

In addition to the colors measured with a given angular size (Table 2), we have computed near-IR colors from regions with a given linear size (Table 3). The minimum projected aperture diameter is determined by the spatial resolution of the images and the galaxy distances, and we chose two apertures with projected diameters of 0.5 and 1 kpc. These two apertures are comparable to the size of the **1:1 kpc-scale** torus proposed by Maiolino & Rieke (1995). We have also computed the colors of the annuli with inner radii

0.5 kpc and outer radii 1 kpc. Table 3 lists the angular diameters (in arcseconds) and colors corresponding to the linear sizes 0.5 kpc and 1 kpc in the first and second rows respectively, and the colors corresponding to the 0.5 – 1 kpc annulus in the third row. The listed errors include uncertainties due to both the photometric calibration and the determination of the sky level. Because of the large distance of Mrk 463E+W, we were not able to obtain its colors in 0.5 and 1 kpc diameter apertures; in the case of NGC 5252, we list only the 1 kpc and the 1 – 2 kpc annulus colors. For NGC 4388 we compute the 3" – 6" annular colors to match the size of the I' -band emission; for the assumed distance $d=17.1$ Mpc, these colors correspond to an annulus 0.25 – 0.5 kpc.

Figure 2a and 2b show color-color diagrams, namely $J - H$ versus $H - K$ and $H - K$ versus $K - I'$. In each diagram, the circular/oval region to the left represents the colors of bulges of normal spiral galaxies, which match the colors of a late-type stellar population (Willner et al. 1984), whereas the circular/oval region to the right represents the typical colors of quasars corrected to zero redshift (Hylland & Allen 1982; Neugebauer et al. 1979). We have assumed a color transformation $L - L' = 0.15$ (Ward et al. 1982) when using photometry from previous work. The effects of two magnitudes of visual extinction (Rieke & Lebofsky 1985) are represented by the arrow in the upper left corner. The solid lines are the “mixing curves” representing the colors of the sum of a late-type stellar population and either a blackbody component (presumed to be representative of hot dust) with temperatures $T = 600, 800, 1000$ and 1200 K (indicated next to the curves) or nebular emission (only in the $J - H$ versus $H - K$ diagram). The pure nebular component represents the colors produced by hydrogen and helium continuum and line emission (see Alonso-Herrero et al. 1996a for details). The numbers indicate the ratio of the dust luminosity to the stellar luminosity at K , $L_{\text{dust}}/L_{\text{stell}}$ (with loci shown by dashed lines) or the ratio of the nebular luminosity to the stellar luminosity. Open and filled circles represent the 0.5 kpc and 1.0 kpc-aperture colors respectively, joined for each galaxy, while

the star-like symbols are the colors of the annuli.

Figures 2a and 2b confirm the conclusion that the near-IR colors of the central regions of Seyfert 1.5 – 2 galaxies may be explained by a combination of emissions from an evolved stellar population and hot dust, possibly with some extinction effects. It is clear from both diagrams that the fraction of emission from the hot dust component increases for smaller apertures, and must therefore be concentrated near the nucleus. The central $J - H$ and $H - K$ colors can be fully accounted for by emission from an evolved stellar population in only two galaxies - NGC 30S1 and NGC 3393. For the rest of the galaxies, the $L_{\text{dust}}/L_{\text{stell}}$ ratios in the 0.5 kpc aperture are between $\simeq 0.5$ and $\simeq 3$. The most extreme colors are those of NGC 1068. ‘11C’ dust temperatures mostly range between ~ 600 and 1200 K, which is in good agreement with the average $K - L'$ color temperatures (1010 ± 180 K) found by McAlary & Rieke (1988) for an X-ray selected sample of Seyfert galaxies. When comparing these diagrams with figures 4 and 5 in Alonso Herrero et al. (1996b), where colors in a $3''$ diameter aperture were plotted, it is noticeable that the scatter in the near-IR colors is significantly reduced. This reduction in scatter is likely the result of our plotting colors in apertures of a given *linear* diameter which are generally smaller than $3''$. It is also clear from Table 2 that large aperture colors (i.e., those including most of the galaxy) tend to resemble the colors of normal spiral galaxies, except for NGC 4151 and NGC 4253 which still show quite red $H - K$ colors even in $30''$ apertures. The $J - H$ and $H - K$ colors of the 0.5-1 kpc annuli are less affected by dust emission than those of the central regions, and correspond quite well to the colors of normal galaxies; only the colors of NGC 4253 remain very red. In at least some galaxies (e.g., Mrk 348, Mrk 573, NGC 1068 and NGC 4151) the $K - L'$ colors of the annulus cannot be explained as emission from an evolved stellar population plus extinction effects. Rather, the annular $K - L'$ colors seem to reflect a combination of an evolved stellar population with hot dust in emission, with the fraction of K -band emission from hot dust being smaller than for the small nuclear aperture. The $K - L'$ colors

of the annulus in NGC 2110, NGC 2992, NGC 3081, NGC 4388 and NGC 5252 could be simply the colors of an evolved stellar population reddened by a foreground extinction of $A_V \simeq 2$ –4 mag.

Although the above model successfully explains the observed nuclear colors, a more realistic model in the context of the unified model would be desirable. Different geometries and physical sizes have been proposed for the hot dust close to the central engine, including a warped thin disk (Sanders et al. 1989), and a dusty torus extending over a few hundred parsecs in which the hot dust is located in the inner wall (Krolik & Begelman 1988, Pier & Krolik 1993, Granato & Danese 1994, Maiolino & Rieke 1995). In the dusty torus scenario the existence of differential reddening between the stars and the hot dust is predicted, since the torus may be optically thick even in the mid-IR. Here we examine the possibility that the near-IR colors are produced by a combination of starlight not significantly reddened ($A_V \leq 2$ mag), and hot dust much more reddened ($A_V \simeq 0$ –40 mag). The results are illustrated in Figures 2c and 2d, which again are color-color diagrams. In each plot, the dashed line shows how the color changes as the ratio of the intrinsic (unobscured) dust luminosity at K to the stellar luminosity at K is varied: $L_{\text{dust}}/L_{\text{stell}} = 0.5$ –5 (numbers next to the curves). These dashed lines correspond to the solid lines in Figures 2a and 2b. In Figures 2c and 2d we only plot the results for two dust temperatures: $T = 1200$ K and 600 K in $J - H$ versus $H - K$, and $T = 1200$ and 800 K in $H - K$ versus $K - L$. The solid lines represent the mixing curves of the colors of a normal spiral galaxy (unobscured) and the colors of hot dust emission (reddened by visual extinctions from $A_V = 0$ to $A_V = 40$ mag) for the different ratios of dust emission to the galaxy emission in K . On these lines, the tick marks are located every 10 magnitudes of visual extinction. Foreground reddening is indicated by the arrow on the upper left corner. Note that in Figure 2d the dashed lines for the 800 K-mixing curve illustrate how the $L_{\text{dust}}/L_{\text{stell}}$ ratio changes for the various assumed dust extinctions. These results can be readily compared with the data plotted in Figures 2a

and 2b. Clearly, most of the 0.5 kpc nuclear $J - H$, $H - K$ and $K - L'$ colors can be also explained as produced by a mixture of an old stellar population and hot dust emission with a temperature $T = 1200$ K, the latter component reddened by between $A_V \approx 5$ and ≈ 30 mags. The ratio of dust emission to the stellar emission, as derived from these diagrams of the nuclear colors, is between $\frac{L_{\text{dust}}}{L_{\text{stell}}} = 1$ and 6 in Figure 2c and between $\frac{L_{\text{dust}}}{L_{\text{stell}}} = 0.5$ and 10 in Figure 2d. The 1 kpc colors are reproduced with the same dust temperature and A_V , but smaller values of $\frac{L_{\text{dust}}}{L_{\text{stell}}}$. Only the nuclear colors of NGC 1068 require a lower dust temperature ($T = 800$ K), with $\frac{L_{\text{dust}}}{L_{\text{stell}}} \approx 10$ and $A_V \approx 25$ mag. The derived dust temperature for NGC 1068 agrees quite well with the effective dust temperature fitted by Pier & Krolik's (1993) models. Note however that although the models incorporating the extinguished dust emission do not provide in general statistically better fits than the models with a mixture of stellar light and unreddened dust, they provide a better constraint to the dust temperature.

Since the emission from hot dust seems to make a significant contribution to the observed NIR colors of our sample of Seyfert galaxies, one expects that the NIR spectroscopic absorption features of stars should be diluted by the non-stellar continuum. The dust emission clearly dilutes the CO band (at $2.29 \mu\text{m}$) in the nuclear spectrum of NGC 1068 (see figure 3 in Origlia, Moorwood, & Oliva 1993), with a non-stellar contribution at $2.29 \mu\text{m}$ of about 83% or equivalently $\frac{L_{\text{dust}}}{L_{\text{stell}}} = 4.9$. This result is in good agreement with our two limiting estimates for the ratio of dust emission to the stellar emission in K from Figures 2b and 2d, that is, $\frac{L_{\text{dust}}}{L_{\text{stell}}} = 1$, $T(\text{dust}) = 600$ K for the unreddened dust model, and $\frac{L_{\text{dust}}}{L_{\text{stell}}} = 10$, $T(\text{dust}) = 800$ K for the model with extinguished dust ($A_V = 25$ mag). For NGC 2110 Oliva et al. (1995) estimate that the stars contribute approximately 80% of the total continuum at $2.29 \mu\text{m}$ or $\frac{L_{\text{dust}}}{L_{\text{stell}}} \approx 0.25$ for a slit of $4''$. From our 1 kpc-aperture photometry we infer $\frac{L_{\text{dust}}}{L_{\text{stell}}} = 0.50$ with no significant A_V for the dust, consistent with the finding of Oliva et al. (1995).

So far we have compared the NIR colors of our sample of Seyfert galaxies with the expectations for normal galaxies. However, it is of interest to compare the actual surface brightnesses on the scales probed (e.g., radius 0.5 kpc, and the 0.5-1 kpc annulus). Peletier & Barcellis (1997) present NIR Sill'fZdCC' brightness profiles of a complete sample of 30 nearby SO to Sbc galaxies. We have compared the K -band surface brightness profiles of the Seyfert galaxies with those of spiral galaxies with similar morphological type and redshift. For all our Seyfert galaxies except NGC 1068, NGC 4151 and NGC 4253 we find surface brightness profiles similar to those of spiral galaxies, with differences ranging from 0.1 to 0.8 mag arcsec⁻² for radial distances between 0.5 and 1 kpc, and for the inner 0.5 kpc. The surface brightnesses of the Seyferts NGC 1068, NGC 4151 and NGC 4253 at 0.5-1 kpc radius are 1 - 2 mag arcsec⁻² brighter than the normal galaxies. Interestingly, these three galaxies show the reddest $H - K$ colors for the 0.5 and 1 kpc-diameter apertures. From our small sample of Seyfert galaxies we cannot however derive any statistically significant conclusions as to whether the surface brightnesses of the nuclear and circumnuclear regions of Seyfert galaxies are substantially brighter than those of normal galaxies.

3.2. The L' -band imaging

Thermal imaging ($\lambda > 3 \mu\text{m}$) has number of advantages over shorter near-IR wavelengths for studying the non-stellar light at the center of active galaxies. It has already been shown that contamination by stellar emission is much smaller at L' (or L) than at shorter wavelengths; the non-stellar contribution at L' is between 30 and 90% of the total emission in apertures with sizes between 3 and 10'' (McAlary & Rieke 1988, Alonso-Herrero et al. 1996b). In addition, dust with an equilibrium temperature $T \simeq 1000 - 1300$ K has its emission peak close to $3 \mu\text{m}$. A few L' -band (or L -band) imaging studies of active galaxies have shown that the nuclear sources appear to be very compact at this wavelength with

only a very small contribution from the host galaxy. Examples of such compact sources include the radio galaxies Cygnus A (Djorgovski et al. 1991), Centaurus A (Turner et al. 1992) and PKS 0634--205 (Simpson, Ward, & Wilson 1995), the Seyfert 2 galaxies NGC 1386, MCG -5-23-16 and IRAS 195 S0---1S1S (Alonso-Herrero et al. 1996b) and the Seyfert 1 galaxies NGC 7469 (Mazzarella et al. 1994') and Mrk 231 (Zhou, Wynn-Williams, & Sanders 1993).

When determining the nuclear contribution to the total emission from a galaxy at optical and near-IR wavelengths, the usual procedure involves deconvolving the profile into different components, typically an unresolved nuclear source, a bulge and a disk. However, because of the compact nature of the sources and the small contribution from the underlying galaxy, such an approach is not feasible at L' , and so a different method has been adopted. Our approach is similar to that used by McLeod & Rieke (1995) and Forbes et al. (1992), and involves the assumption that a point spread function (PSF) from observations of a star is a good representation of the unresolved light from the nuclear point source. The azimuthally averaged radial surface brightness profile of the galaxy is first obtained. Due to the small area covered by the L' -band images, there are no stars in the field, and therefore a standard star observed shortly before or after the galaxy is used for the PSF. The stellar PSF brightness profile is then scaled to match the central galaxy brightness. Note that in doing so we may overestimate the point source brightness since there is some stellar flux at the nucleus itself. In Figure 3 we show four examples of the L' -band brightness profiles (expressed in mag arcsec^{-2} , represented as squares with their associated errors. The PSF brightness profiles are the star-like symbols. A Gaussian function has been fitted to each stellar PSF, with the value of the seeing in arcseconds (FWHM) indicated at the top of each panel. The Gaussian fit is represented by the dashed line.

The contribution of the unresolved source is found by integrating both the galaxy and

standard star brightness profiles within two apertures: a fixed $3''$ diameter aperture and an aperture comprising the surface brightness limit at L' as indicated for each galaxy in the caption of Figure 1. Finally the ratios of the unresolved to the total L' flux are calculated for both apertures. The results are presented in Table 4, where column (1) gives the name of the galaxy, column (2) the FWHM (in arcsec) obtained by fitting a Gaussian function to the standard star, column (3) the fraction of the total flux within a $3''$ diameter aperture which is unresolved, column (4) the maximum radius used to produce the L' galaxy brightness profile, column (5) the fraction of the total flux within the aperture given in the previous column which is unresolved, and column (6) the magnitude of the unresolved source at L' .

From Table 4 it can be seen that the contribution of the unresolved source to the L' -band flux within a $3''$ aperture exceeds 80% for all the galaxies in our sample except NGC 2992 and NGC 2110. In our sample, the unresolved source accounts for between 26% and 100% of the L' -band emission integrated over the brightness surface limit. This result was anticipated by the non-stellar fractions calculated by different methods, such as comparing the $K - L$ colors of normal galaxies and Seyfert galaxies (McAlary & Rieke 1988, Alonso-Herrero et al. 1996b). For the four galaxies in common with the study of Alonso-Herrero et al. (1996b) - NGC 2110, NGC 4388, Mrk 348 and Mrk 573 - we find good agreement (to within the errors) for the contribution of the unresolved source to the integrated flux within a $3''$ aperture.

3.3. The origin of the circumnuclear L' emission in NGC 1068 and NGC 4151

As noted in Section 3.1 there are four galaxies in our sample (NGC 1068, NGC 1111, Mrk 348 and Mrk 573) showing 0.5 -- 1 kpc annular $H - K$ and $K - L'$ COIOS which cannot be accounted for with a reddened normal stellar population. However for two of these galaxies (Mrk 348 and Mrk 573) the angular sizes used to obtain the 0.5 kpc and 1 kpc color

are relatively small, and it is possible that some of the annular L' flux is from the core of the PSF. For this reason, these two galaxies are not included in the following analysis. The two most likely mechanisms producing the extra L' flux in the circumnuclear region for NGC 106S and NGC 4151 would be scattering of the intrinsic Seyfert spectrum by clouds in the annulus region, or in-situ heating of the dust by hot stars. The scattering efficiency needed to reproduce the non-stellar annular L' flux is too high, since the ratio of the annular non-stellar flux to the nuclear flux (assuming that all the 0.5 kpc flux is non-stellar) is approximately 0.1 for both NGC 106S and NGC 4151. In addition in the case of NGC 106S the extended L' band emission is aligned with the stellar bar, such an alignment would not be expected if scattered light from the nucleus was the origin of the extended emission.

We now consider the possibility that the extended L' emission is produced by in-situ heating of dust by hot stars. First we need to determine the excess L' luminosity, i.e., the non-stellar luminosity within the annulus. We assume that the stars in the annulus have $K - L' = 0.45$, and use Figure 2b to determine both the fraction of the annular K -band luminosity emitted by the stars and the dust temperature. We assume that the dust absorbs the UV radiation produced by a population of hot stars and reradiates the energy in the L' band. All the non-stellar L' flux will be reradiated dust emission, since the types of stars responsible for heating the dust are hot and bluish and therefore will not have much intrinsic NIR emission. For the purposes of our simple calculation we will assume that only dust with temperatures ranging between 700 K and 900 K (this dust temperature range is derived from Figure 2b) will be making a significant contribution to the observed non-stellar L' flux of NGC 106S and NGC 4151. Now we need to determine a reasonable value for the re-radiative efficiency to convert the UV luminosity emitted by the stars to infrared reradiation by the dust. In a rough approximation this efficiency can be expressed as,

$$f = \frac{\Omega}{4\pi} e^{-\Delta\tau} g$$

where Ω is the solid angle subtended by the dust, g takes into account that only a fraction of the total dust emission comes out in the L' band, and for the considered temperature range $\Delta\tau$ is the optical depth needed to reduce the temperature of the radiation field from 900 K to 700 K. We model g as the ratio of the $3.4 - 4.1 \mu\text{m}$ emission to total emission for **800** K blackbody. By restricting our calculations to a single temperature, we do not have to take into account the actual temperature distribution, which is too model dependent. For a radiation field ($L = \text{UV}$) we have,

$$\frac{L_{\text{UV}}}{4\pi r^2} \approx \tau Q = \epsilon \sigma T^4 \quad (2)$$

where τ is the optical depth, Q is the absorption efficiency of the grains, ϵ is the emission efficiency of the grains and σ is the Stefan-Boltzmann constant. The maximum value for the re-radiative efficiency (i. e., assuming $\Omega = 4\pi$) turns out to be $f = 0.16$ in our simple model. The estimated dust luminosities within the $0.5 - 1$ kpc annulus are $1.633 \pm 0.10 \times 10^{42} \text{ erg s}^{-1}$ and $6.09 \pm 0.10 \times 10^{41} \text{ erg s}^{-1}$ for NGC 1068 and NGC 4151 respectively. Hence the lower limits to the UV luminosity needed to produce the observed L' luminosities would be $L_{\text{UV}} \simeq 1.0 \times 10^{43} \text{ erg s}^{-1}$ and $L_{\text{UV}} \simeq 3.8 \times 10^{42} \text{ erg s}^{-1}$ respectively. Panelli et al. (1997) have recently observed both galaxies with the Ultraviolet Imaging Telescope, and showed that they display extended UV emission suggesting the presence of massive star formation in their host galaxies. These authors determine that the starburst disk of NGC 1068 dominates the observed UV luminosity ($\simeq 80\%$), whereas the disk of NGC 4151 contributes about 10% of the total UV luminosity. From the near and far UV monochromatic fluxes and the size of the UV disk emission to the total emission given in Panelli et al. (1997), we estimate the disk UV luminosities of NGC 1068 and NGC **4151** to be $L_{\text{UV}}(\text{disk}) \simeq 2.2 \times 10^{43} \text{ erg s}^{-1}$ and

$L_{UV}(\text{disk}) \simeq 4.2 \times 10^{42} \text{ erg s}^{-1}$ respectively, which would suffice to account for the annular I' emission in these two galaxies. Summarizing, this simple calculation shows that in-situ heating of dust by hot stars is a plausible mechanism to explain the annular non-stellar emission in these two galaxies.

3.4. Morphology of the central and circumnuclear regions

Mulchaey & Wilson (1995) have found a good correlation between the orientations of the [O III] $\lambda 5007$ emission line region and the green continuum on a scale of a few arcsecond in a sample of Seyfert galaxies, and have suggested that this is due to the presence of an extended featureless continuum component. Such an extended featureless continuum was originally proposed by Tran (1995) in order to explain the optical polarizations seen in a sample of Seyfert 2 galaxies.

McLeod & Rieke (1995) have found that the rate of occurrence of bars in Seyfert galaxies is similar to that in normal galaxies. However, Maiolino et al. (1997) find that asymmetries (namely, the occurrence of bars, interactions and distorted morphologies) are more frequently present in hosts of Seyfert 2 nuclei than in field galaxies, and in some cases are probably linked to an enhanced rate of star formation. Moreover, recent optical and near-IR surface photometry studies of galaxies selected as candidates for having at least double bars (See for instance Wozniak et al. 1995, Friedli et al. 1996) have shown that the proportion of Seyfert galaxies amongst these double-barred systems is high. These conflicting results are undoubtedly due to the subjective nature of what constitutes a distortion. This naturally raises the question of whether such structures are more common in Seyfert galaxies than in otherwise similar normal galaxies. In addition, small scale red structures have been detected in near-IR color maps of the central or circumnuclear regions of some Seyfert galaxies (e. g., NGC 5252 Kotilainen & Prieto 1995; Mrk 348 Simpson

et al. 1996) or in residual images obtained after subtracting a smooth model based on fitting elliptical isophotes to near-IR images (e. g., NGC 7469 - Mazzarella et al. 1994; NGC 985 - Appleton & Marcum **1993**), or in optical images obtained with *HST* (e.g., NGC 5252 - Tsvetanov et al. 1996; Mrk 573- Capetti et al. **1996**).

It is of interest, then, to study in detail the morphologies of the central and circumnuclear regions of our sample of galaxies in order to determine whether or not there is an alignment between the near-IR continua and the EELRs (including ionization cones) and whether bars and red structures such as those mentioned above are commonly present in Seyfert galaxies with EELRs. To determine the morphology of obscuration and/or the presence of large scale stellar bars, we have built smooth models of the *J*- and *K*-band images. For those galaxies observed during both runs, the isophotal analysis has been performed on both sets of images. Models consisting of best-fitting elliptical isophotes were constructed (by using the IRAF ELLIPSE routine) in order to reproduce the radial brightness profile, ellipticity and the orientation (P. A.) of the galaxy. The *J*- or *K*-band image of each galaxy was then divided by the model, which is assumed to represent the stellar brightness distribution. The resulting images will reveal any isophotal deviations from elliptical symmetry, such as bars, spiral arms, HII regions, etc. This surface photometry technique used in the near-IR has proven to be extremely useful for both tracing the old stellar population and detecting bars and disks (Friedli et al. 1996). In Table 4, columns (i), (8) and (9) we give the P. A. of the 3''-diameter (major axis) isophote in the *J*, *H* and *K* bands for those galaxies observed with the smaller pixel size (1996 Dec data), and for a 5''-diameter isophote for the 1995 Jan data. We chose a larger diameter for the latter data because, as mentioned in Section 2, wind shake produced artificial elongations in some images, so that the shapes of the innermost isophotes may not be reliable. In Figure 4 we show plots of the surface brightness profile, ellipticity and P. A. as a function of the semi-major axis of the fitted ellipse in *J* for each galaxy in our sample except Mrk 463E+ W'. When data existed

from both observing runs, we plot both fits. In all cases we find an excellent agreement for the fitted ellipticity and P.A. in the overlapping regions of the galaxy.

In what follows, the results obtained for each galaxy in our sample are examined for the presence of isophotal deviations from elliptical symmetry. The structures seen in the model-divided images are compared with those in optical line-emission images; the possible co-alignment of these structures with the axes of the EELRs, radio emission and overall galaxy orientation is also examined. Although bars and other non-axisymmetric structures are clearly revealed in the model-divided images, we also examine the P.A. and ellipticity plots to check that any such structures are not artifacts. According to McLeod & Rieke (1995), the existence of a bar is indicated when the ellipticity grows steeply with radius and then falls off to the ellipticity of the disk of the galaxy, and at the same time the P.A. remains constant over the range of increasing ellipticity. In Table 5 we give the orientation of the outer parts of the galaxy as derived from the ellipse fitting of the lowest isophotes (1995 Dec data) in column (2), the orientation of the outer parts of the galaxy derived from optical data in column (3), the P.A. of the [O III] $\lambda 5007$ and radio emissions in columns (4) and (5) respectively, and references for the optical and radio data in column (6). Column (i') summarizes those structures found in the model-divided images and their corresponding orientations. We do not discuss NGC 4151 here, because the continuum images are contaminated by diffraction spikes from the bright nucleus, and are therefore not suitable for this kind of analysis.

Notes on individual galaxies

Mrk 348

The near-IR and optical properties of the Seyfert 2 galaxy Mrk 348 have been extensively discussed by Simpson et al. (1996). To summarize, after subtracting a model for the surface brightness of the galactic bulge, they found a red linear structure (interpreted as an edge-on

disk) in the near-IR continuum which runs approximately $2''$ (500 pc) E-W and is unresolved in the *N-S* direction. An *HST* $[0\text{ III}] \lambda 5007$ image (Capetti et al. 1996) shows that the central emission is confined to a linear structure $0''.45$ in size, with P.A. $\approx 155^\circ$, while on a larger scale the $[0\text{ III}] \lambda 5007/\text{H}\alpha + [\text{N II}]$ emission is extended over several arcseconds and shows a biconical morphology with axis at P.A. $\approx 170^\circ$ (Simpson et al. 1996; Mulchaey et al. 1996). Capetti et al.'s (1996) optical continuum image reveals obscuration across the nuclear region with a scale of less than 50 pc . The resolution of our images is not good enough to determine whether this obscuration is associated with the elongated red feature seen in the near-IR images.

In Figure 4a we show the ellipticity and major axis P.A. as a function of the semi-major axis of the fitted ellipse in the *J* band. The P.A. of the L' -scale isophote in the *J*, *H* and *K* band images is close to 90° (consistent with the orientation of the elongated red feature found by Simpson et al. 1996). However the fitted P.A. should be taken with caution because of the low values of the ellipticity. Within a region of size equal to or smaller than $3''$ (1.3 kpc), 90% of the L' -band emission appears to be unresolved.

Mrk 573

When fitting elliptical isophotes to the *J* and *K* band images, a remarkable twist in the major axis of the isophotes is found at a radial distance of $4''.5$ (see Figure 4b), changing rapidly from P.A. $\approx 0^\circ - 10^\circ$ in the outer isophotes to P.A. $\approx 50^\circ - 90^\circ$ in the inner isophotes. This is consistent, with the presence of a stellar bar extending over approximately $90''$ (9.8 kpc) at P.A. $= 0^\circ$ as also found in the *HST* 5500 \AA continuum image (Capetti et al. 1996). In addition to this large-scale bar, Pogge & DeRobertis (1995) find evidence for the presence of an inner stellar bar in this galaxy, oriented nearly E-W (P.A. $\approx 100^\circ$), perpendicular to the large-scale bar. Our data support this result, since the ellipticity increases steeply from the nucleus out to radial distance $r \approx 2''$, while the P.A. remains

approximately constant (Figure 4b). This galaxy therefore shows evidence for a “bar within bar” situation.

Capetti et al. (1996) constructed an axisymmetric model from the *HST* 5500 Å continuum image and found a dust lane which spans 1″ (500 pc) and is significantly warped. The variation of the P.A. and ellipticity with radius found by these authors compares well with our results, differences in the ellipticity of approximately 0.1 are found in the inner 2″. The *HST* [O III] λ5007 image (Schmitt & Kinney 1996) reveals emission extending 2″ to the NW with a total opening angle of 70°, whose substructure is apparently dominated by the interaction of the radio jet with the ISM. The P.A. of the 5″-diameter ellipse at *J*, *H* and *K* (Table 4) are all similar and consistent with the orientation of the inner bar.

NGC 1068

In Figure 5 we present the *J*-band image divided by the model of NGC 1068 superimposed on the *J*-band continuum image (note that due to the brightness of this galaxy, the *K*-band image shows a ghost image of the nucleus, and therefore the fitting is not reliable at that position). The solid contours (emission in excess over the galaxy model) clearly show an impressive stellar bar and the inner spiral arms. The bar runs from NE to SW at position angle P.A. = 45° – 50°, approximately 36″ (4 kpc) in extent, and between 3 and 6″ (300 – 600 pc) in width, in good agreement with the results found by Thronson et al. (1989) at 1.6 and 2.2 μm. Furthermore, the resemblance of the deviations from the symmetric model to the “lumpy” morphology seen in the CO map presented by Helfer & Blitz (1995) is remarkable, although the P.A. of the molecular bar is slightly different (≈ 63°). The orientation of the bar differs from the kinematic and photometric major axis of the galaxy disk (P.A. = 50° ± 9°, Baldwin, Wilson, & Whittle 1987). The [O III] λ5007 emission line region of this galaxy has a conical shape extended by 7″.5 at P.A. = 35°, with opening angle 45° (Evans et al. 1991). The *L'*-band image shows emission within 5″ of the nucleus, with

85 % of the total emission unresolved and associated with the nucleus, whereas the extended emission at this wavelength follows the orientation of the J , H and K inner isophotes (Figure 1.c).

In addition to the bar, there is a ring-like structure or perhaps inner spiral arms in the J band image, with outer diameter $\simeq 36''$, similar to the $10\ \mu\text{m}$ structure found by Telesco et al. (1984) and the morphology in the UV/red continuum color map presented in Pogge & DeRobertis (1993). These authors show that roughly half of the mid/far-IR emission from NGC 1068 originates from the Seyfert nucleus and half from the disk surrounding it, with the disk being powered by star formation. The near-IR colors within an annulus with inner diameter $30''$ and outer diameter $36''$ (i. e., bracketing the ring) are: $J - I = 0.78$ and $H - K = 0.27$, Consistent with the colors of normal spiral galaxies, whereas the colors of the nucleus itself (for a $3''$ diameter aperture) are extremely red: $J - I = 1.15$, $H - K = 1.10$ and $K - I' = 3.70$, and can best be represented in terms of a combination of unreddened starlight plus obscured hot dust, emission (with a blackbody temperature $T \simeq 800\text{ K}$), as explained above. The ratios of the total fluxes in the ring to the nuclear emission (defined as the region interior to the stellar bar, within a $6''$ diameter aperture) in the observed images are 0.50, 0.65 and 0.37 at J , H and K band respectively, which demonstrates the increasing dominance of the nuclear emission towards longer wavelengths.

NGC 2110

The central part of the J and K -band model-divided images (not shown here) displays only an unresolved structure located at the center of the galaxy, and a red "blob" at a distance $9''$ (2 kpc) from the center in the SE direction, which is possibly an H II region or a foreground star. The major axis P.A. of the $3''$ diameter isophote in the J , I and K images is $170^\circ - 174^\circ$, with the major axis converging to 163° at larger radial distances, which coincides with the optical overall galaxy orientation of $160^\circ - 166^\circ$ (Wilson, Baldwin,

& Ulvestad 1985). The contribution of the unresolved nucleus at L' appears to be smaller than for most galaxies in our sample, with the nucleus contributing only 42% of the total flux within a $3''$ diameter aperture.. The *HST* [0 III] $\lambda 5007$ emission-line image of this galaxy displays a curved extended emission morphology, which extends from the nucleus over $0''.7$ along the NW direction, and then bends towards the NE, with a total extent of $0''.9$ (Mulchaey et al. 1994). The P.A. of the near-nuclear [0 III] $\lambda 5007$ and green continuum isophotes in ground-based images is 158° (Mulchaey & Wilson 1995) in good agreement with the near-IR P.A. at radial distances greater than $2''.7$.

NGC 2992

NGC 2992 is an Sa galaxy seen almost edge-on and interacting with NGC 2993. The K -band image divided by the model of NGC 2992 is presented in Figure 6 (the image derived from the J -band data shows a similar morphology). The model-divided result for this galaxy displays a very complex structure. In the innermost regions, there is a structure at P.A. $\approx 37^\circ$ seen in excess, extending approximately $6''$ (1.3 kpc) from the nucleus to the NE and $11''$ (2.4 kpc) to the SW. The spiral arms are also visible. The overall galaxy orientation as derived from the P.A. plot is P.A. $\approx 23^\circ$ (see Figure 4c).

The $H\alpha + [N II]$ image presented in Colbert et al. (1996) shows the presence of a dust lane which separates the line emission into a double-lobed shape, extending about $5'' - 15''$ in the SE-NW direction. A careful alignment of our model-divided image with the image in Colbert et al. (1996) shows that the location of the structure seen in our image does not correspond with the position of the dust lane. Due to the high inclination of this galaxy we cannot discern the nature of this structure. This galaxy also shows extended emission at L' (Figure 1c), with the contribution of the unresolved component to the total observed flux being relatively small (26%) in comparison with what is found for most of the galaxies in our sample. The P.A. of the $3''$ isophotes in the J , H and K bands are all

consistent with the orientation of the dust lane, while at larger radial distances the P.A. become $\simeq 23 - 26^\circ$, presumably tracing the underlying stellar distribution. The nuclear $K - L'$ colors of this galaxy are the least red of any in our sample because the L' unresolved component contributes a relatively small fraction of the total emission.

NGC 3081

The optical morphology of this galaxy is extensively discussed by Buta (1990), who found it to possess three rings of diameters $13''$ (nuclear), $67''$ (inner) and $150''$ (outer) together with a weak bar which is enveloped by the inner ring. Our elliptical isophote analysis (performed out to a radial distance of $30''$) appears to show two bars. Figure 7 displays the J -band data results, and shows the inner ring described in Buta (1990) in the continuum image (grey-scale). The nuclear bar has a P.A. $\simeq 117^\circ$ (consistent with the P.A. of the nuclear bar in Buta's description), extending up to $6''.6$ (1.5 kpc) on either side of the nucleus. The inner bar has an average P.A. $\simeq 11^\circ$. The major axis position angle of this galaxy (i. e., orientation of the outer ring) is P.A. $\simeq 123^\circ \pm 4^\circ$ (Buta 1990). From the J -band continuum image, there is evidence for a ring of 11 HII-regions with inner diameter $45''$ (10.4 kpc), whose orientation is consistent again with that of the inner bar. The bars and the rings show evidence for star formation according to Wozniak et al. (1995), who found similar structures in their optical continuum images; the isophotal analysis performed by Friedli et al. (1996) on near-IR images of this galaxy agrees quite well with our results. The H α and H δ -based images obtained by Pogge (1989) and Storchi-Bergmann et al. (1996) show the HII regions of the inner ring congregating at the end of the inner bar. The H α image of the nucleus appears to be rather asymmetric and extended along the major axis of the galaxy P.A. $\simeq 125^\circ$ (Pogge 1989), with a diameter of $10''$, and whose orientation and size are consistent with those of the nuclear bar seen in our images.

The P.A. for the 3σ isophote in the J , H and K bands are similar ($102^\circ - 112^\circ$), but

coincide with the P.A. of neither bar. The small-aperture $J - H$ and $H - K$ colors (see Tables 2 and 3) of this galaxy seem to be similar to those of elliptical or spiral galaxies with no signs of activity (see the study of the near-IR colors for galaxies of different morphological types in the Coma Cluster by Gavazzi, & Trinchieri 1989), whereas the $K - L'$ color, although redder than that of a normal spiral galaxy, is much less red than the colors shown by other Seyfert 2 galaxies in our sample. The $J - H$, $H - K$ and $K - L'$ annular colors resemble those of a spiral galaxy. It is also noticeable that the near-IR colors do not show large changes with increasing aperture size.

NGC 3393

NGC 3393 is a SBab galaxy, the spiral arms of which form an almost complete ring. The J -band image presented in Figure 1g does not cover the full extent of the galaxy (the two bright objects located NW of the center of the galaxy are stars according to Tsvetanov & Petrosian 1995). The faint outer spiral arms can be seen in the J -band image. The J -band model-divided image (Figure 5) traces the stellar bar along P.A. $\simeq 160^\circ$ - 165° . A number of H II regions are seen at the end of the bar, with positions in good agreement with those found in Tsvetanov & Petrosian's image. The innermost regions of the model-divided image display an unresolved central structure together with a linear structure (perhaps a faint bar) in P.A. $\simeq 145^\circ - 150^\circ$. The presence of the outer bar can be inferred from the variation of the ellipticity and P.A. as a function of the distance from the nucleus (Figure 4g). The high-resolution *HST* [O III] $\lambda 5007$ emission line image of this galaxy (Schmitt & Kinney 1996) reveals S-shaped emission extending .5" along P.A. $\approx 55^\circ$. The emission extends over 1".5 on either side of the nucleus, roughly E-W, and then curves towards the N and S, in the same sense as the spiral arms.

The J , H and K -band 3" isophote P.A. are 160° , 149° and 142° respectively, roughly perpendicular to the orientation of the [O III] $\lambda 5007$ emission. NGC 3393 shows near-IR

colors which resemble those of normal spiral galaxies or unreddened starbursts, with no evidence for dust emission or a large amount of extinction, even for the smallest aperture. We did not observe this galaxy at I' , but, Boisson & Durret (1986) did and found that the near-IR emission is dominated by stellar emission, with no excess emission over their I.-band stellar template.

NGC 4253

NGC 4253 (Mrk 766) is a barred SBa galaxy with optical overall orientation P. A. $\approx 69^\circ$ (MacKenty 1990). Indeed, the J -band model-divided image (see Figure 9, also seen in the direct image, Figure 1 i) clearly indicates the presence of a bar (i.e., positive galaxy minus model residuals) at P. A. $\simeq 110^\circ$, which may be compared with the P. A. $\simeq 60^\circ$ of the outer isophotes. The bar reaches $7''$ (2.7 kpc) to the SE and $9''$ (3.4 kpc) to the NW, in good agreement with the size derived by McLeod & Rieke (1983.5). This galaxy also appears to have an asymmetric arm on its northern side which is well traced by the model-divided image, and a ring-like structure extending to the NE, SE and W. The [O III] $\lambda 5007$ morphology (Mulchaey, Wilson, & Tsvetanov 1996) shows a core elongated E-W with fainter extensions in the NW-SE direction. The H α line-emission exhibits a ring-like structure to the E with line-ratios well described by H II region models (González-Delgado & Pérez 1996). The high excitation gas forms a V-shaped morphology to the SE of the nucleus (in P. A. $\simeq 120^\circ$ and extending for $5''$), with a weaker NW extension. The P. A. of the [O III] $\lambda 5007$ and H α emissions are 112° and 107° (Mulchaey et al. 1996), respectively, in good agreement with the direction of the stellar bar. The P. A. of the $3''$ isophotes in J , H and K band are $102 - 114^\circ$, orientations similar to those of the bar and possible colic.

NGC 4388

NGC 4388 is a highly inclined ($i \simeq 72^\circ$) Seyfert 2 galaxy which shows substantial dust obscuration. This galaxy displays a complex morphology in emission-line images (Pogge

19SS; Corbin, Baldwin & Wilson 19SS). The $\text{H}\alpha + [\text{N II}]$ image highlights H II regions in the disk of the galaxy. The $[\text{O III}] \lambda 5007$ image, however, shows a conical shape along $\text{P.A.} = 35^\circ$ extending approximately $40''$ (3.3 kpc) NE and $20''$ (1.6 kpc) SW of the nucleus. Pogge (19SS) argues that the $[\text{O III}] \lambda 5007$ emitting gas is likely to be either photoionized by a nuclear continuum or shock ionized.

On large scales our J and K -band model-divided images clearly trace the H II regions in the spiral arms of this galaxy (positive residuals in Figure 10). In addition, another two structures outlined by positive residuals can be seen, the first extending at least $16''$ (1.3 kpc) along $\text{P.A.} \simeq 45^\circ$, and the second approximately $12''$ (1 kpc) along $\text{P.A.} \simeq 228^\circ$.

NGC 5252

NGC 5252 is a SO galaxy classified as a Seyfert 1.5-1.9, with a large-scale ionization bi-cone (Tadhunter & Tsvetanov 1989). The overall galaxy orientation is at $\text{P.A.} = 15^\circ$ both in the near-IR (see Figure 4k) and in the optical (Prieto & Freudling 1996). The J and K -band model-divided images (not shown here) clearly trace the stellar disk at this position angle. The innermost regions of the model-divided images reveal the presence of a linear structure (also seen in the $J - K$ color map, not shown here) elongated in the E-W direction and unresolved in the N-S direction with an extension $\simeq 3''$ (2 kpc). Kotilainen & Prieto (1995) found a similar structure in their near-IR to optical color maps. Although the red linear feature seen in the NGC 5252 color map is real, we believe it is not a result of actual structure in the galaxy, but rather reflects the combination of the high axial ratio of the stellar distribution, and the presence of a bright unresolved nuclear source at K . The nuclear source (which is presumably transmitted radiation from the Seyfert 1 nucleus) contributes $\sim 35\%$ of the peak flux at K and therefore produces a much redder $J - K$ color at the nucleus. Along the major axis of the galaxy, the surface brightness of the stellar component drops slowly, and so the red nucleus has little effect on the overall color beyond

the seeing disk. Along the minor axis, however, the stellar surface brightness decreases much more rapidly, so the nucleus has an effect on the color over a greater distance, thereby producing an elongated feature in the color map. This interpretation is consistent with the fact that this feature is more closely aligned perpendicular to the major axis of the galaxy than to the ionization cone. In addition, scaling the J image to match the K image in a circumnuclear annulus, and then subtracting it, reveals only a nuclear point source, and no E-W structure.

4. DISCUSSION

In general we do not find any clear trend between the orientation of the FELRs and that of the IR continuum structures near the center of the galaxies. However, we do find bars or “bars within bars” in five out of the twelve galaxies studied here, with two galaxies (NGC 2992 and NGC 4388) too inclined to detect a bar. It has been argued that bars might be responsible for transporting gas to the nuclei of galaxies. Codes modeling the gas flow in and around bars (see Athanassoula 1994 for a review) show that both the axial ratio and the strength of the bar influence the form of the shock loci: weak bars have curved shock fronts, with their concave part towards the bar major axis, while strong bars produce straight fronts. As noted by Athanassoula (1994) it appears that the most promising mechanism for pushing gas to the center of the galaxy is that of “bars within bars”. The numerical simulations of the formation of double bars in galaxies carried out by Friedli & Martinet (1993) show that it is possible to form two bars simultaneously, together with a gaseous ring and eventual dissolution of the inner bar, or the formation of a large scale bar first and then a second bar, and ultimately dissolution of the two bars. In both cases, an increase of the gas mass within the inner $0.2 - 1$ kpc is predicted, with the gas being compressed into a region 10% - 20% of the bar length. Further, the gas is expected to settle

into a disk with rotation axis along the bar (e. g., Durisen et al. 1983). This disk could then collimate both the radio ejecta and the ionizing photons along the bar (Morris et al. 1983). If these predictions are correct we might expect to see an alignment between the inner bar and the FFLRs. The inner bars in NGC 106S, NGC 30S1 and NGC 4253 are approximately aligned with their FFLRs, which seems to support this scenario. Mrk 573 and NGC 3393 show evidence for double bars, but the orientation of their FFLRs seems unrelated to their directions.

Finally by inspecting Table 4, columns (7) through (9), and Table 5, column (4), we can explore the possibility of an alignment between the emission line gas and the IR continuum on small scales. As mentioned above, such an alignment has been found in the optical (Mulchaey & Wilson 1995) for a sample of Seyfert galaxies of early types with well defined emission line axes, and explained as possibly due to the presence of an extended featureless continuum. Assuming that the typical errors in the determination of the P. A. of the $[O III] \lambda 5007$ line emission are 10° (Mulchaey & Wilson 1995), we find that there is alignment between the line emission and the near-IR continuum in four galaxies - NGC 106S, NGC 2110, NGC 30S1 and NGC 4253; of these, only NGC 2110 does not contain a bar. The alignment found in the near-IR for some galaxies could, in principle, contradict Mulchaey & Wilson's (1995) interpretation because any such a featureless continuum would be swamped by starlight in the near-IR. Among those galaxies with a near-IR alignment, two of them (NGC 2110 and NGC 4253) are in common with Mulchaey & Wilson (1995). Note however that NGC 5252 has a similar major axis P. A. in optical and near-IR continua, but these directions are not aligned with the line emission. Although it is not possible to derive any general conclusions from our small sample of Seyfert galaxies with FFLRs, it appears that non-axisymmetric structures may be playing some role in transporting material into the central regions. However there is no clear relationship between the orientations of bars and FFLRs.

5. CONCLUSIONS

We have carried out a near-IR imaging study of a sample of type 1.5 - type 2 Seyfert galaxies with EELRs, including some of the best studied examples of their class. The good observing conditions together with the small pixel size used have allowed us to obtain high-quality images, which have been analyzed in detail in order to gain insight into the structure of the inner and circumnuclear regions of the galaxies. In addition to standard synthetic aperture photometry (i. e., performed with fixed apertures in arcseconds), we have also obtained the near-IR colors of regions with linear diameters of 0.5 and 1 kpc, along with an annulus between these sizes. Previous studies of the near-IR properties of Seyfert galaxies have shown that the $J - H$, $H - K$ and $K - L'$ central colors (i. e., in a 0.5 kpc diameter aperture) are well explained by a mixture of an evolved stellar population plus a component of hot dust emission. Here we propose a more realistic model (in view of the dusty torus scenario) in which the non-stellar source (hot dust with temperature $T \simeq 1200$ K) is significantly reddened ($t_V \approx 5 - 30$ mag), whereas the starlight is unreddened. There is little evidence from the $J - H$ and $H - K$ colors outside 0.5 kpc for emission from hot dust. However, the $K - L'$ circumnuclear (i.e., 0.5- 1 kpc annulus) colors of some of the galaxies in our sample do show some indication of hot dust emission, although its contribution is smaller than in the nucleus. We argue that this extranuclear hot dust is heated by young stars.

The L' -band imaging has allowed us to quantify the extension of the emission at this wavelength, which shows both an unresolved and an extended component. We have also found that the unresolved source of the emission accounts for between 26% and 100% of the emission at L' band.

Finally, we have fitted elliptical isophotes to the near-IR images in order to produce smooth models of the stellar distribution. The model-divided images have been examined

for isophotal deviations from elliptical symmetry, such as bars, spiral arms and dust lanes. The structures found in the model divided images have been compared with the orientations of the F, ELRs, galaxy disk and radio sources. We have found stellar bars in NGC 106S and NGC 4253, and evidence for double bars (or “bars within bars”) in Mrk 573, NGC 30S1 and NGC 3393. The orientation of the inner bars of NGC 106S, NGC 30S1 and NGC 4253 is approximately aligned with that of their EFELRs, but in Mrk 573 and NGC 3393 the bars and the EFELRs are not aligned (contrary to the conclusion of Axon & Robinson 1996). Our results suggest that there is no simple relationship between bars and EFELRs.

We thank the anonymous referee for helpful comments. During the course of this work A. A.-II. was partially supported by the National Aeronautics and Space Administration on grant NAG 5-3042 through the (University of Arizona. C.S. was supported by NASA, through grants NAGW-3268 and HSTGO-5411 from the Space Telescope Science Institute, which is operated by AURA, Inc., under NASA contract 5-26555, and by NATO through grant 675183. A. A.-H. would like to thank the Department of Astrophysics, University of Oxford, where part of this work was carried out, for their warm hospitality. Part of this work was carried out by the Jet Propulsion Laboratory, California Institute of Technology under a contract with NASA.

This work is based on observations collected at UKIRT. The United Kingdom Infrared Telescope is operated by the Joint Astronomy Centre on behalf of the U.K. Particle Physics and Astronomy Research Council. This research has made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory.

Figure Captions

Fig. 1--- (a) Mrk 348. Contour plots on a logarithmic scale of the J and L' band images of the sample of Seyfert galaxies observed during the 1995 Jan run. North is up and east is to the left. Note that the 64×64 pixel L' -band images have been plotted at the same scale as the J -band images. The lowest level displayed in the J -band contour plot is 21.39 mag arcsec⁻², and successive contours are separated by 0.75 mag arcsec⁻². The lowest level displayed in the L' -band contour plot is 14.62 mag arcsec⁻², and successive contours are separated by 0.75 mag arcsec⁻².

Fig. 1--- (b) Mrk 573. The lowest level displayed in the J -band contour plot is 21.29 mag arcsec⁻², and successive contours are separated by 0.75 mag arcsec⁻². The lowest level displayed in the L' -band contour plot is 14.86 mag arcsec⁻², and successive contours are separated by 0.75 mag arcsec⁻².

Fig. 1.- (c) NGC 1068. The lowest level displayed in the J -band contour plot is 17.18 mag arcsec⁻², and successive contours are separated by 0.40 mag arcsec⁻². The lowest level displayed in the L' -band contour plot is 13.08 mag arcsec⁻², and successive contours are separated by 0.75 mag arcsec⁻².

Fig. 1.- (d) NGC 2110. The lowest level displayed in the J -band contour plot is 19.95 mag arcsec⁻², and successive contours are separated by 0.50 mag arcsec⁻². The lowest level displayed in the L' -band contour plot is 14.10 mag arcsec⁻², and successive contours are separated by 0.60 mag arcsec⁻².

Fig. 1--- (e) NGC 2992. The lowest level displayed in the J -band contour plot is 20.38 mag arcsec⁻², and successive contours are separated by 0.50 mag arcsec⁻². The lowest level displayed in the L' -band contour plot is 14.76 mag arcsec⁻², and successive contours are separated by 0.50 mag arcsec⁻².

Fig. 1--- (f) NGC 3051. The lowest level displayed in the J -band contour plot is $19.53 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.40 \text{ mag arcsec}^{-2}$. The lowest level displayed in the L' -band contour plot is $15.15 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.40 \text{ mag arcsec}^{-2}$.

Fig. 1--- (g) NGC 3393. The lowest level displayed in the J -band contour plot is $20.21 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.60 \text{ mag arcsec}^{-2}$.

Fig. 1.- (h) NGC 4151. The lowest level displayed in the J -band contour plot is $18.72 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.50 \text{ mag arcsec}^{-2}$. The lowest level displayed in the L' -band contour plot is $12.96 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.75 \text{ mag arcsec}^{-2}$.

Fig. 1--- (i) NGC 4253. The lowest level displayed in the J -band contour plot is $19.10 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.60 \text{ mag arcsec}^{-2}$.

Fig. 1.- (j) NGC 4388. The lowest level displayed in the J -band contour plot is $20.88 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.50 \text{ mag arcsec}^{-2}$. The lowest level displayed in the L' -band contour plot is $14.91 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.50 \text{ mag arcsec}^{-2}$.

Fig. 1.- (k) NGC 5252. The lowest level displayed in the J -band contour plot is $21.16 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.60 \text{ mag arcsec}^{-2}$. The lowest level displayed in the L' -band contour plot is $14.55 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.75 \text{ mag arcsec}^{-2}$.

Fig. 1.- (l) Mrk 4634+W. The lowest level displayed in the J -band contour plot is $21.72 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.60 \text{ mag arcsec}^{-2}$. The lowest level displayed in the L' -band contour plot is $14.17 \text{ mag arcsec}^{-2}$, and successive contours are separated by $0.75 \text{ mag arcsec}^{-2}$.

Fig. 2--- (a) and (b) $J - H$ versus $H - K$ and $H - K$ versus $K - L'$ diagrams. Open and filled circles are the 0.5 and 1 kpc-aperture colors respectively, while stzLr-like symbols represent the circumnuclear (0.5 — 1 kpc-annulus) colors. Maximum errors (which apply to the annular colors) are plotted in the lower right part of the diagrams: $A(J - H) = 0.13$, $\Delta(H - K) = 0.12$ and $A(K - L') = 0.12$ mag. See text for a detailed **explanation of the mixing curves and other symbols**.

Fig. 2-- (c) and (d) $J - H$ versus $H - K$ and $H - K$ versus $K - L'$ diagrams showing the effects of differential extinction between the stars (unreddened) and the hot dust emission (reddened by $A_V = 0 - 40$ mag). The numbers next to the curves indicate the ratio of the dust emission to the galaxy emission ($\frac{L_{\text{dust}}}{L_{\text{stell}}}$). See text for details.

Fig. 3--- Surface brightness **profiles** (in mag arcsec⁻²) in the L' band for four galaxies **of the sample**. The squares represent the observed galaxy **data points** with their associated **errors**. The star-like symbols are data points for the PSF brightness profile computed from the standard star observed shortly before or after the galaxy, and scaled to match the central brightness of the galaxy. The data point spacing corresponds to the pixel size of the images, i.e., 0".286 **pixel-1**. The dashed line is a Gaussian function fit to the stellar profile.

Fig. 4. - Surface brightness profile, ellipticity and major axis P.A. (and their corresponding errors) as a function of the semi-major axis of the fitted ellipse in the J band for each galaxy in our sample except Mrk 463. When the galaxy was observed during both runs, for the ellipticity and P.A. we plot the 1995 Jan data as filled squares, and the 1996 Dec data as open circles.

Fig. 5.- NGC1068. The black **contours** represent the J -band image divided by a **slit100111** model on a logarithmic scale. The grey scale map is the J -band continuum image on a logarithmic scale. The size of the image is 40" x 40". Note that in this figure and successive figures, contours greater than 1 (implying the galaxy emission is brighter than the model)

are shown as solid lines, whereas contours less than 1 (implying the galaxy emission is fainter than the model) are plotted as dashed lines. The contours represent differences between the galaxy emission and the model at levels 3%, 6%, 12% and 25%. Orientation is north up, east to the left. $10''$ corresponds to 1.1 kpc. The model-clipped image shows an impressive bar along $P.A. = 45^\circ$, together with some features which could be associated with dusty regions, as suggested by the similarity with the CO morphology (see figure 2 in Helfer & Blitz 1995). Note also the presence of a number of H II regions or dust features in the ring of star formation exterior to the bar.

Fig. 6--- NGC 2992. The black contours, plotted on a logarithmic scale, represent the result of dividing the K -band image by a smooth model and smoothing with a 2-pixel boxcar. The contours represent differences between the galaxy emission and the model at levels 3%, 6%, 11% and 22%. The grey scale map is the K -band continuum image on a logarithmic scale. $10''$ corresponds to 2.2 kpc. The model-divided image shows a very complex morphology. There is a structure seen in emission located at $P.A. = 35^\circ$, which may be compared with the galaxy disk major axis in $P.A. = 23^\circ$. The model-divided image contours clearly trace the position of the spiral arms in the outer regions. There is also structure roughly perpendicular to the galactic plane and extending over $10''$ from the nucleus to the NW.

Fig. 7--- NGC 3051. The black contours, plotted on a logarithmic scale, represent the result of dividing the J -band image by a smooth model and smoothing with a 4-pixel boxcar. The contours represent differences between the galaxy emission and the model at levels 2%, 5% and 15%. The grey scale map is the J -band continuum image on a logarithmic scale. $10''$ corresponds to 2.3 kpc. The model-divided image clearly shows the presence of two bars, a nuclear bar elongated in $P.A. = 118^\circ$, and an inner bar (which is more diffuse and extended) in $P.A. = 71^\circ$. Note that the elliptical isophote model was computed out to a radial distance of $30''$. Also apparent in the grey scale map is a diffuse ring of H II regions

surrounding the inner bar, and a number of H II regions.

Fig. 8--- NGC 3393. The black contours, plotted on a logarithmic scale, represent the result of dividing the *J*-band image by smooth model and smoothing with a 2-pixel boxcar. The contours represent differences between the galaxy emission and the model at levels 1%, 3%, 5%, 10% and 20%. The grey scale map is the *J*-band continuum image on a logarithmic scale. The size of the image is 40" x 40", 10" corresponds to 4 kpc. The positive residuals trace the stellar bar running NW-SE in P.A. $\simeq 160 - 165^\circ$. Note also the presence of an inner structure with P.A. $\simeq 145 - 150^\circ$

Fig. 9--- NGC 4253. The black contours, plotted on a logarithmic scale, represent the result of dividing the *J*-band image by a smooth model and smoothing with a 2-pixel boxcar. The contours represent differences between the galaxy emission and the model at levels 2%, 5% and 12%. The grey scale map is the *J*-band continuum image on a logarithmic scale. 10" corresponds to 3.5 kpc. There are clear residuals from the bar running SE-NW in P.A. $\simeq 10$ SO. The model-divided image also traces the asymmetric spiral arm on its northern side, together with a ring-like structure to the NE, SE and W.

Fig. 10.- NGC 4388. The black contours, plotted on a logarithmic scale, represent the result of dividing the *J*-band image by a smooth model and smoothing with a 2-pixel boxcar. The contours represent differences between the galaxy emission and the model at levels 2%, 4%, 8%, 19% and 43%. The greyscale map is the *J*-band continuum image on a logarithmic scale. 10" corresponds to 0.5 kpc. The model-divided image contours reveal the presence of a number of structures: spiral arms with embedded H II regions which extend along the overall galaxy orientation ($i.l. \simeq 95^\circ$), and also two structures projecting out of the plane to the NE and SW at P.A. $\simeq 45^\circ$ and P.A. $\simeq 228^\circ$ respectively, which might be related to the high excitation extranuclear gas.
